

1 Q. **Reference: Economic and Technical Assessment, page 21 (p. 55 pdf)**

2 Citation:

3 With an electrical interconnection and the 25 kV voltage conversion of southern
4 Labrador distribution systems, the fault levels on these systems will increase as
5 shown in Table 5, therefore minimizing the effect of voltage flicker during motor
6 starting.

7 a. Please explain the relationship between fault levels, “available fault current”, and voltage
8 flicker.

9

10

11 A. The available fault current is the maximum amount of current that can be delivered to the
12 electrical equipment (customer) under a fault or motor starting condition. The amount of motor
13 starting or fault current available will increase as the distribution system voltage increases.

14 The voltage flicker is a transient phenomenon that occurs when large loads are switched on the
15 system causing an instantaneous change in voltage. Usually this is experienced when large
16 amount of inrush current is required to start a motor. In these cases, a short-term dip in voltage
17 is experienced due to the short-term increase in current flow. This can cause lights to flicker or
18 motor operation to be interrupted. The magnitude of voltage flicker depends on the amount of
19 available fault current at a particular location. If the available fault current is high, the voltage
20 flicker associated with a certain amount of inrush current will be less. Newfoundland and
21 Labrador Hydro (“Hydro”) communicates inrush current limits to customers to limit voltage
22 flicker.

23 The 25 kV voltage conversions of the southern Labrador distribution systems will create a more
24 robust distribution system with higher amounts of available fault current. The increased fault
25 current will allow Hydro’s customers to start larger motors without impacting other customers
26 on the system with voltage flicker.
